- Slow Slaves (Peripherals)
- Bus Hierarchies
- Accessing Control Registers in C
- Conclusions

Embedded Systems

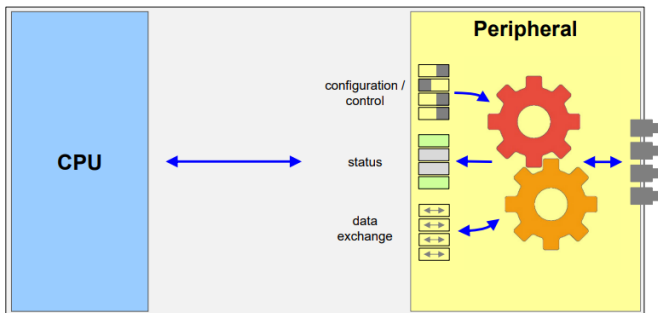

- low cost (usb sticks, consumer electronics)
- low power (sensor networks, mobile devices)
- small size (smart cards, wearables)
- real time (anti-lock brakes, process control)
- reliability (medical devices, automotive)
- extreme environment (space, automotive)

Single Chip Solution ⇒ CPU with integrated memory and peripherals

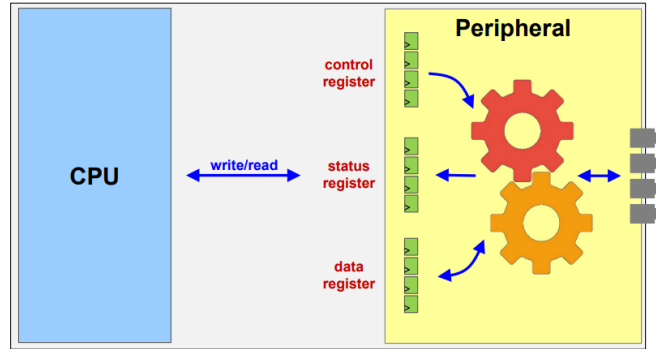

Peripherals

- configurable hardware blocks of a microcontroller
- accepts a specific task from the CPU, executes task and returns result (status, e.g. task completion, error)
- oftentimes interfaces to the outside world many (not all) interact with external MCU pins (grey things very right side of image)
- examples: GPIO, UART, SPI, ADC...

Peripheral Registers the CPU controls and monitors Peripherals through registers

- Registers are arrays of flip-flops (storage elements with two states, i.e. 0 or 1)
- Each flip-flop stores one bit of information
- CPU writes to and reads from registers

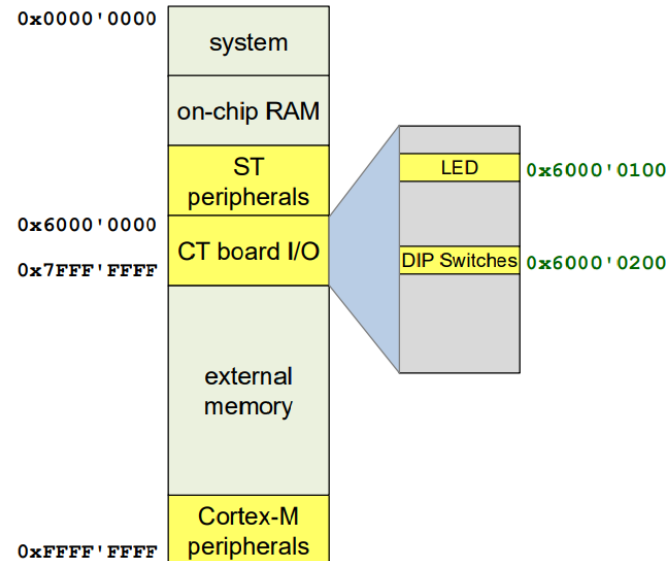

A Peripheral typically has multiple registers that can be categorized as:

- **Control Registers**
enable CPU to configure the peripheral
- **Status Registers**
enable CPU to monitor the peripheral
- **Data Registers**
enable CPU to exchange data with the peripheral

Memory-mapped Peripheral Registers Distinction between LEDs and DIP switches on the CT-Board:

- Control register → controls states of LEDs
- Status register → monitors states of DIP switches

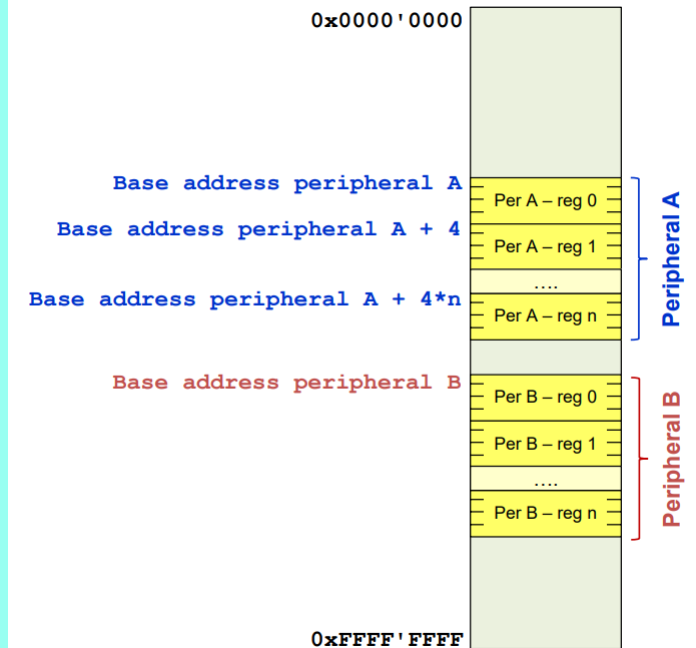

CPU access to individual peripheral registers

- ARM & STM map the peripheral registers into the memory address range
- Reference Manual shows the defined addresses
Example SPI (Serial Peripheral Interface)

Each column shows a single flip-flop

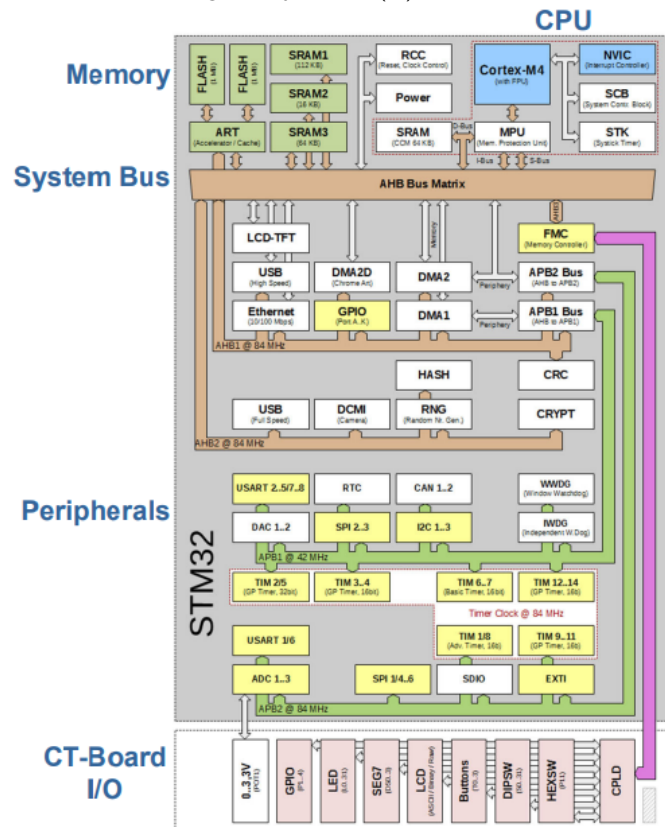

CPU read/write to peripheral registers How does the CPU write to and read from peripheral registers?

- CPU reads/writes to peripheral registers
- CPU uses memory-mapped I/O to access peripheral registers
- CPU uses load/store instructions to access peripheral registers

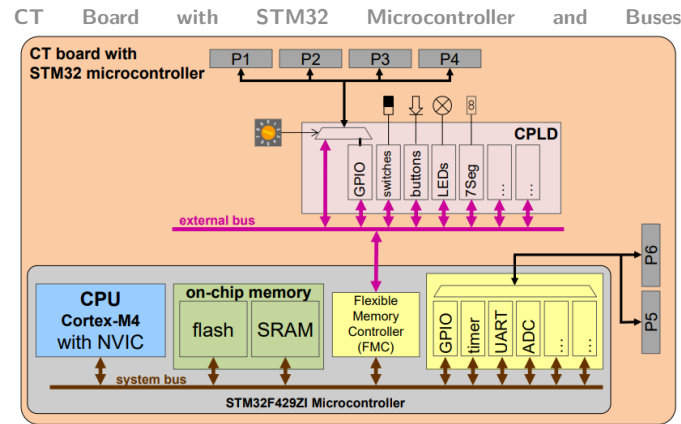

⇒ System Buses

STM32 Microcontroller with CPU, on-chip memory, and peripherals interconnected through the system bus(es)

A distributed system with parallel (simultaneous) processing of data in many peripherals. All under the supervision of the CPU.

Note: ARM calls their system buses AHB (ARM High-performance Bus) and APB (ARM Peripheral Bus). On complex chips, it is state-of-the-art to partition the system bus into multiple interconnected buses.

System Bus

- Interconnects CPU with memory and peripherals
- CPU acts as master: initiating and controlling all transfers
- Peripherals and memory act as slaves: responding to requests from the CPU
- System bus is a shared resource

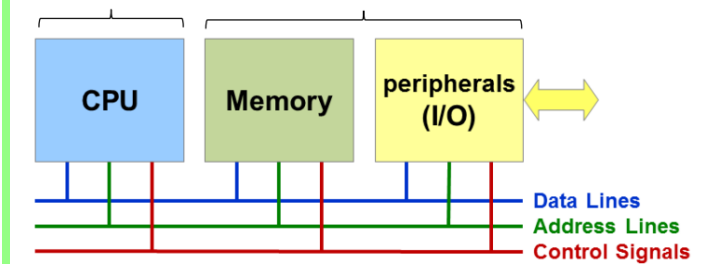

Bus Specification

- **Protocol and operations**
- **Signals**
 - Number of Signals
 - Signal descriptions
- **Timing**
 - Frequency
 - Setup and hold times
- **Electrical properties** (not in exam)
 - Drive strength
 - Load
- **Mechanical requirements** (not in exam)

Signal Groups

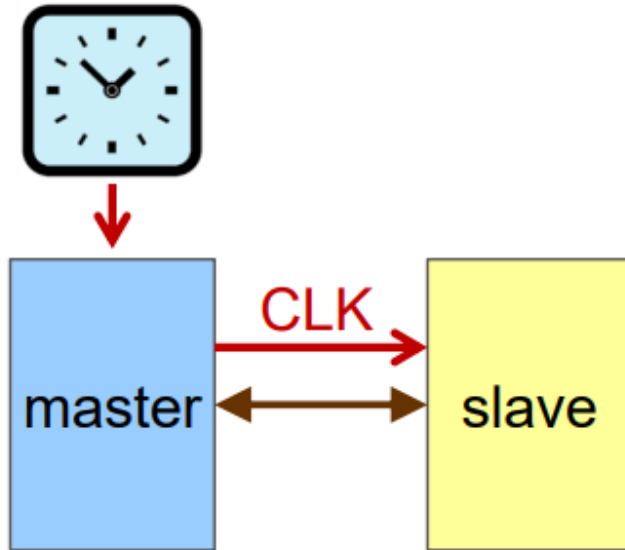

- **Address lines**
 - Unidirectional: from Master to slaves
 - Number of lines → size of address space
- **Data lines**
 - Bidirectional (read/write)
 - Number of lines → data bus width (8, 16, 32, 64 parallel lines of data)
 - Example: Cortex-M has 32 address lines *rightarrow* 4GB address space *rightarrow* 0x00000000 to 0xFFFFFFFF
- **Control signals**
 - Control read/write direction
 - Provide timing information
 - Chip select, read/write, etc.

Bus Timing Options

Synchronous

- Master and slaves use a common clock
Often a dedicated clock signal from master to slave, but clock can also be encoded in a data signal
- Clock edges control bus transfer on both sides
- Used by most on-chip buses
- Off-chip: DDR and synchronous RAM

Asynchronous

- Slaves have no access to the master clock
- Control signals carry timing information to allow synchronization
- Widely used for low data-rate off-chip memories
⇒ parallel flash memories and asynchronous RAM

Multiple devices driving the same data line

What if one device drives a logic 1 (V_{cc}) and another device drives a logic 0 (Gnd)?

⇒ Electrical short circuit! *⇒ bus contention* (SSStreitigkeit")

Figure only shows output paths, input paths are not shown.

CPU defines who drives the data bus at which moment in time:

- write CPU drives bus *⇒* all slave drivers disconnected
- read CPU releases bus *⇒* one slave drives bus (selected through values on address lines, other slave drivers disconnected)

Electrically disconnecting a driver is called **tri-state** or **high-impedance** (Hi-Z) state. (switch)
